Abstract The objective of this study is to cross-validate 34 Coupled Model Intercomparison Project Phase 5 (CMIP5) historical simulations of precipitation against the Global Precipitation Climatology Project (GPCP) data, quantifying model pattern discrepancies, and biases for both entire distributions and their upper tails. The results of the volumetric hit index (VHI) analysis of the total monthly precipitation amounts show that most CMIP5 simulations are in good agreement with GPCP patterns in many areas but that their replication of observed precipitation over arid regions and certain subcontinental regions (e.g., northern Eurasia, eastern Russia, and central Australia) is problematical. Overall, the VHI of the multimodel ensemble mean and median also are superior to that of the individual CMIP5 models. However, at high quantiles of reference data (75th and 90th percentiles), all climate models display low skill in simulating precipitation, except over North America, the Amazon, and Central Africa. Analyses of total bias (B) in CMIP5 simulations reveal that most models overestimate precipitation over regions of complex topography (e.g., western North and South America and southern Africa and Asia), while underestimating it over arid regions. Also, while most climate model simulations show low biases over Europe, intermodel variations in bias over Australia and Amazonia are considerable. The quantile bias analyses indicate that CMIP5 simulations are even more biased at high quantiles of precipitation. It is found that a simple mean field bias removal improves the overall B and VHI values but does not make a significant improvement at high quantiles of precipitation.

1. Introduction

Numerous studies have emphasized that water resources are sensitive to climate change, and thus, water resources management and planning strategies should be adjusted accordingly [e.g., Seager *et al.*, 2007; Stoll *et al.*, 2011; Sivakumar, 2011; Cayan *et al.*, 2008; Wood *et al.*, 1997]. One of the key climate variables is precipitation, which plays a dominant role in the hydrologic cycle. Developing future water resources management and planning strategies thus requires estimation of current and future precipitation magnitude and variability [Wehner, 2013].

In the past several decades, global climate models have been used to estimate future projections of precipitation [Intergovernmental Panel on Climate Change (IPCC), 2007]. However, these projections are inherently uncertain and often are difficult for decision makers to interpret [e.g., Liepert and Previdi, 2012; Reichler and Kim, 2008; Brekke and Barsugli, 2012; Schubert and Lim, 2013; Feddema *et al.*, 2005; Min *et al.*, 2007]. Quantification of biases and uncertainties in climate simulations of precipitation thus is fundamental to understanding the reliability of climate simulations for future water resources management. Gleckler *et al.* [2008] introduced several metrics for performance analysis of climate models and emphasized the need to go beyond the mean statistics for comprehensive analysis of climate model performance. Moise and Delage [2011] and Schaller *et al.* [2011] subsequently presented alternative approaches and metrics for evaluating seasonal precipitation simulations. AghaKouchak and Mehran [2013] introduced a number of volumetric indicators for validation and verification of climate model simulations.

Since the inception of the of the Coupled Model Intercomparison Project Phase 3 (CMIP3) by the World Climate Research Programme Working Group on Coupled Modelling, evaluation of coupled ocean-atmosphere simulations of historical climate relative to available observational data has become an especially strong scientific focus [e.g., Bony *et al.*, 2006]. Indeed, future developments and improvements in global climate models (GCMs) rely heavily on their rigorous and informative validation.

Generally, climate model simulations are known for poor representation of frontal, convective, and mesoscale processes [Van Weverberg *et al.*, 2013]. Numerous studies have evaluated various aspects of precipitation in the CMIP3 model simulations. Phillips and Gleckler [2006], for example, evaluated CMIP3 simulations of seasonal mean continental precipitation amounts and concluded that many of these differed markedly from several observational estimates. They also noted that the ensemble mean model precipitation was generally closer to the observations than that of any individual CMIP3 model. Several studies focused on the common errors and/or frequency and intensity of CMIP3 daily precipitation simulations [e.g., Dai, 2006; Sun *et al.*, 2007; Stephens *et al.*, 2010; Brown *et al.*, 2010]. Dai [2006] evaluated the mean spatial patterns, precipitation intensity, frequency, and diurnal cycle. The results showed that many climate models simulated unrealistic double Intertropical Convergence Zone precipitation patterns, though most models captured the overall precipitation pattern. Furthermore, Dai [2006] showed that the CMIP3 simulations produce light rain (1 to 10 mm) too frequently [see Brown *et al.*, 2010; Stephens *et al.*, 2010; Wilcox and Donner, 2007; Sun *et al.*, 2007].

Brown *et al.* [2010] demonstrated that models capture the synoptic regimes well and concluded that uncertainties in precipitation simulations are due to problems in simulating the characteristics of precipitation within different synoptic regimes. In a recent study, Catto *et al.* [2013] argued that climate models often underestimate frontal precipitation estimates. Biases have been reported in model precipitation simulations from warm clouds, associated with unrepresentative microphysical parameterizations [Lebsock *et al.*, 2013]. Wehner *et al.* [2010] showed that many climate models underestimated 20 year return values of precipitation and suggested increasing the horizontal resolution could improve estimation of extremes. Ghan *et al.* [2002] showed that improving representation of subgrid variability and surface topography has a significant positive impact on model precipitation simulations [see also Qian *et al.*, 2010].

Following upon CMIP3, the current Coupled Model Intercomparison Project Phase 5 (CMIP5) includes an unprecedented suite of coordinated simulations of historical and future-climate scenarios [Taylor *et al.*, 2012] that are designed to facilitate consideration of the wide range of scientific issues to be addressed in the forthcoming Intergovernmental Panel on Climate Change Fifth Assessment Report. The CMIP5 climate simulations are archived by institutional participants in the Global Organization for Earth System Science Portals that is coordinated by the U.S. Department of Energy's Program for Climate Model Diagnosis and Intercomparison. A comprehensive description of the detailed numerical, dynamical, and physical properties of the CMIP5 models is now in progress [Guilyardi *et al.*, 2013].

In a recent study, Liu *et al.* [2012] evaluated the variability of CMIP5 precipitation simulations and their response to temperature using satellite data and showed that there is generally good agreement (correlation) between model simulations and satellite-inferred observed precipitation anomalies over land, both in the Tropics and globally. In addition, Sillman *et al.* [2013] evaluated models' performance in simulating precipitation extremes at 1–5 day time scales. Hirota and Takayabu [2013] investigated reproducibility of observed precipitation distribution in CMIP5 relative to CMIP3 simulations over the tropical oceans. They showed ensemble mean of CMIP5 simulations exhibited slightly higher skill score compared to CMIP3 ensemble mean. Gaetani and Mohino [2013] studied the decadal predictability of CMIP5 simulations of the Sahel precipitation and concluded that predictive skills of CMIP5 precipitation simulations vary significantly from model to model. Kumar *et al.* [2013] showed that the CMIP5 ensemble mean precipitation matched very well with that of ground-based observations, while there were substantial biases in the simulation of regional precipitation trends. A number of other studies assessed past and future changes in precipitation based on CMIP5 simulations at regional or global scales [e.g., Chadwick *et al.*, 2013; Joetzer *et al.*, 2013; Hao *et al.*, 2013; Kelley *et al.*, 2012; Kharin *et al.*, 2013; Polson *et al.*, 2013].

The present study evaluates CMIP5 historical simulations of continental precipitation against the Global Precipitation Climatology Project (GPCP) monthly mean observational estimates [Adler *et al.*, 2003] using several quantitative statistical measures. This model evaluation focuses on the years 1979–2005, a period for which long-term and gauge-adjusted satellite observations are available. The remainder of this paper is organized into three sections. The observational data sets are briefly introduced in section 2, while section 3 is devoted to methodology and results. Summary remarks and conclusions are included in Section 4.

2. Data Sets

The GPCP reference data set [Adler *et al.*, 2003] is derived from merged satellite-precipitation data that are bias corrected using thousands of continental rain-gauge observations. The GPCP land algorithm is primarily

based on microwave scattering estimates from low Earth orbit satellites, and geosynchronous infrared estimates. Additional precipitation information is integrated based on data from the Television and Infrared Observation Satellite Operational Vertical Sounder, and outgoing longwave radiation measurements [Adler *et al.*, 2003]. The data set is available as a monthly time series from 1979 onward. GPCP data sets have been validated and widely used in numerous studies [e.g., Bolvin *et al.*, 2009; Huffman *et al.*, 2009]. The ground-based data are assembled by the Global Precipitation Climatology Centre [Rudolf *et al.*, 1994] of the Deutscher Wetterdienst and by the National Oceanic and Atmospheric Administration Climate Prediction Center and used for bias correction of the final product (see Easterling [2013] for the distribution of gauges).

In this study, 34 CMIP5 historical simulations of monthly mean precipitation for the period 1979–2005, and their ensemble mean and median, are validated against the GPCP observations. Because of lack of reference gauge data across oceans, GPCP data over oceans are not bias adjusted. One cannot evaluate biases in CMIP5 simulations with a reference data set having unknown bias. For this reason, this study is limited to evaluation of CMIP5 simulations overland where GPCP data are bias adjusted using thousands of ground-based gauge data [Adler *et al.*, 2003].

All CMIP5 precipitation simulations and GPCP data are regridded onto a common 2 × 2° grid. Table 1 summarizes the CMIP5 models considered in this study. In addition, the results for both the multimodel ensemble mean and median are provided, since the latter is less sensitive to statistical outliers than the former.

Figure 1. Bias (with optimal value = 1) of selected CMIP5 precipitation simulations, and of their ensemble mean and median, all with respect to GPCP observations. White-colored areas indicate “NaN”—undefined or no values.

It should be noted that the model simulations that are designated as “_esm” are historical simulations of climate with atmospheric CO₂ emissions specified in coupled Earth systems models (ESMs) that include a prognostic carbon cycle, but with model-specific dynamical vegetation schemes “turned off.” All the other climate simulations are performed with coupled ocean-atmosphere models in which the historical time series of global atmospheric CO₂ concentrations are prescribed. Although the CO₂ concentration time series in the “_esm” runs are not identical to these prescribed values (owing to model-specific differences in converting CO₂ emissions to concentrations), they are effectively constrained to be very similar.

3. Methodology and Results

Several statistical measures are employed to assess climate model-based historical precipitation simulations. Figure 1 displays the overall biases of climate model simulations relative to observations. The bias B is defined as the sum of monthly precipitation amount P for each CMIP5 model divided by the sum of the corresponding GPCP observations in each $2 \times 2^\circ$ grid box:

$$B = \frac{\sum_{i=1}^n P_{\text{CMIP5}}}{\sum_{i=1}^n P_{\text{GPCP}}} \quad (1)$$

Here n is the number of exceedances of a specified local monthly (daily) precipitation threshold t (which in this case is set equal to 1 mm/d), while, for simplification, the index i signifying each month in the 1979–2005 time series is not included (i.e., $P_{\text{CMIP5}} = P_{\text{CMIP5}i}$ and $P_{\text{GPCP}} = P_{\text{GPCP}i}$). A bias value above (below) 1 thus indicates an aggregate model overestimation (underestimation) of the monthly GPCP precipitation amounts for a particular grid box.

In the Figure 1 mappings of B , the color green indicates where there is little simulation bias, while red (blue) indicates large positive (negative) bias relative to GPCP data (white areas indicate no data in either observations or model simulations). This pertains to most model simulations of precipitation over the eastern

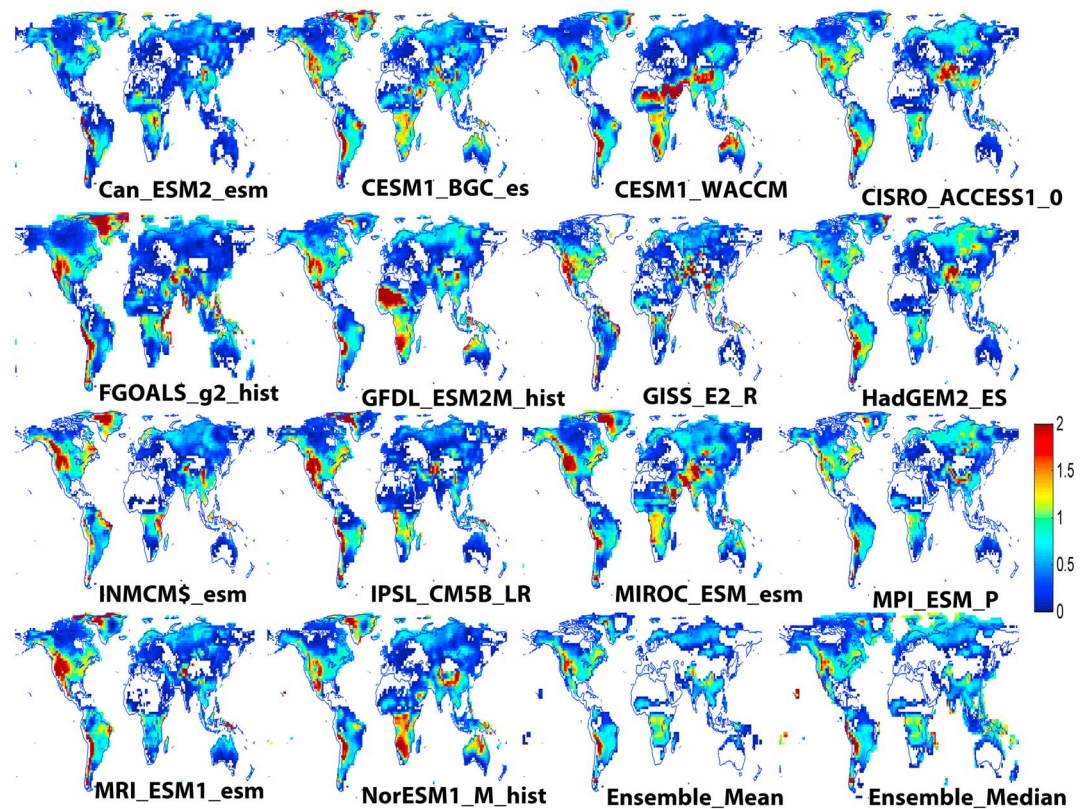

Figure 2. Quantile bias ($t=75$ percentile, QB_{75} with optimal value = 1) maps for selected CMIP5 precipitation simulations, and for their ensemble mean and median, all with respect to GPCP observations.

United States and northern Europe and Asia, but many show a large positive bias (as high as ~ 2) in regions of complex topography such as western North and South America, and southern Africa and Asia, as was also noted for CMIP3 models by Phillips and Gleckler [2006]. In contrast, most models underestimate precipitation over the Saharan and central Asian deserts. Australia and Amazonia are other locations where there are substantial variations in both the sign and magnitude of the biases across individual simulations. On the other hand, the GPCP data may be subject to biases due to the limited availability of ground-based gauge data for bias correction and the limitations of satellite data in estimating orographic precipitation [Sorooshian et al., 2011; Mehran and AghaKouchak, 2014].

In Figure 1, it is also noteworthy that the spatial patterns of the biases of the ensemble mean and median simulations are similar (bottom right panels) and over several regions (e.g., Australia and the Americas) are of lower magnitude than the biases of most of the individual model simulations. From comparing global-average biases B summarized in Table 1; however, the overall global bias of a number of the CMIP5 simulations is seen to be closer to the optimum value of 1 than is that of the ensemble mean ($B=0.89$) and median ($B=0.85$).

It is well known that the bias is not necessarily constant throughout a distribution function but may change at different quantile levels. To further investigate precipitation biases in the CMIP5 simulations, the quantile bias (QB_t), defined as the ratio of monthly precipitation amounts in each simulation to that of the GPCP observations above a specified threshold t (e.g., the 75th percentile of all the local monthly values), can be calculated in each $2 \times 2^\circ$ grid box:

$$QB_t = \frac{\sum_{i=1}^n (P_{CMIP5} | P_{CMIP5} \geq t)}{\sum_{i=1}^n (P_{GPCP} | P_{GPCP} \geq t)} \quad (2)$$

Here $QB_t = 1$ indicates no bias in the simulations, whereas a value above (below) 1 corresponds to a climate model's overestimation (underestimation) of precipitation amount above the specified threshold t , with respect to that of the GPCP observations. Figure 2 displays QB_t values, computed for the 75th percentile

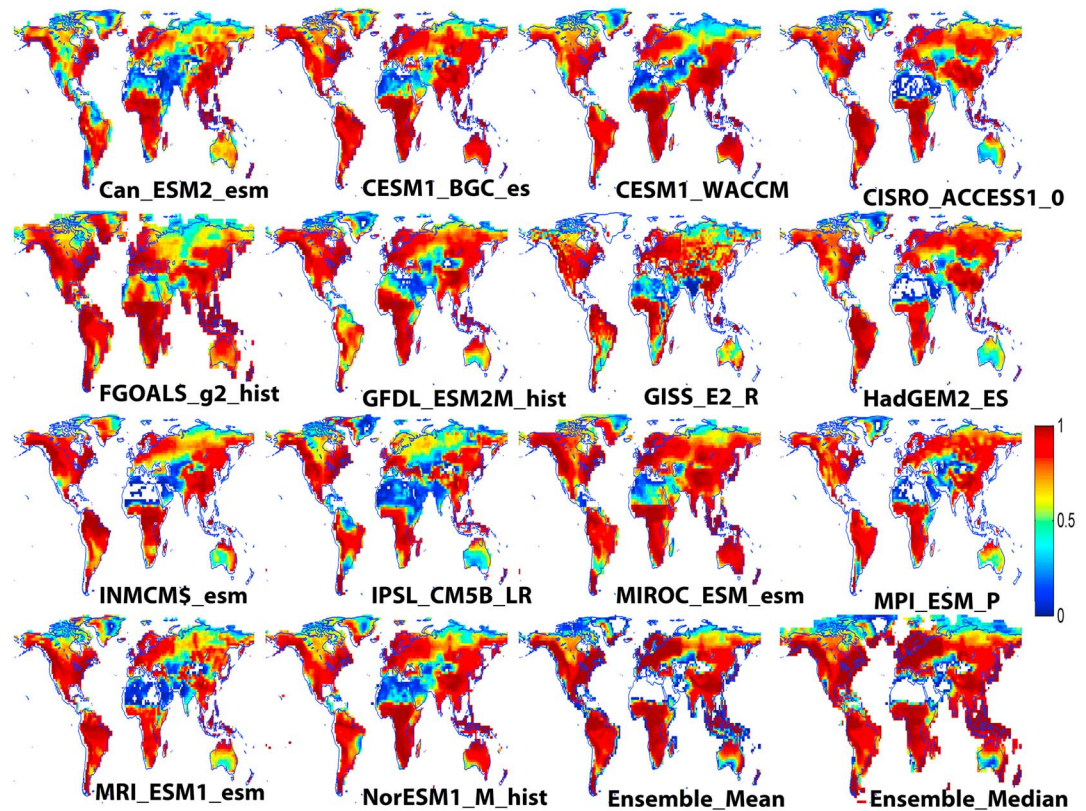

Figure 3. Volumetric hit index (VHI) for $t = 0$ (with optimal value = 1) maps for selected CMIP5 precipitation simulations, and for their ensemble mean and median, all with respect to GPCP observations.

(precipitation values above $t = 75\%$ of the reference data), in the CMIP5 simulations. This figure indicates that the climate model biases apparent in Figure 1 are generally accentuated in the upper tail (i.e., $> 75\%$ quantile) of the GPCP precipitation distribution. While individual CMIP5 models behave somewhat differently from one another, most of their simulations underestimate heavier precipitation amounts over large areas (e.g., Eurasia, Middle East, and northern China), while overestimating them only in certain limited regions (e.g., Amazonia, Central Africa, and United States). Given this general behavior, it is not surprising that the multimodel ensemble mean and median also show large negative biases for observed precipitation amounts $> 75\%$ quantile of the distribution. Such negative biases are even more pronounced for P amounts $> 90\%$ of the distribution (figure not shown for brevity).

Bias and quantile bias describe the overall ratio of simulations over observations and do not provide information on the grid-scale matching of simulated precipitation relative to missed precipitation based on reference observations. The volumetric hit index [AghaKouchak et al., 2011], which measures the volume of precipitation above the threshold (t) detected correctly by climate models with respect to the total simulated and missed precipitation (based on GPCP), can provide such a measure of model performance [Mehran and AghaKouchak, 2014]. For $t = 0$ and $t > 0$, the VHI in each $2 \times 2^\circ$ grid box is defined as [AghaKouchak et al., 2011]

$$\text{for } t = 0 \text{ VHI} = \frac{\sum_{i=1}^n (P_{CMIP5} | P_{CMIP5} > 0 \text{ and } P_{GPCP} > 0)}{\sum_{i=1}^n (P_{CMIP5} | P_{CMIP5} > 0 \text{ and } P_{GPCP} > 0) + \sum_{i=1}^n (P_{GPCP} | P_{GPCP} > 0 \text{ and } P_{CMIP5} = 0)}$$

$$\text{for } t > 0 \text{ VHI} = \frac{\sum_{i=1}^n (P_{CMIP5} | P_{CMIP5} \geq t \text{ \& } P_{GPCP} \geq t)}{\sum_{i=1}^n (P_{CMIP5} | P_{CMIP5} \geq t \text{ and } P_{GPCP} \geq t) + \sum_{i=1}^n (P_{GPCP} | P_{GPCP} \geq t \text{ and } P_{CMIP5} < t)} \quad (3)$$

where P_{CMIP5} = CMIP5 simulations, P_{GPCP} = GPCP observations, n = number of exceedances above threshold t . The ideal VHI score is 1, indicating perfect simulation skill, while 0 corresponds to no skill. In this study, VHI is

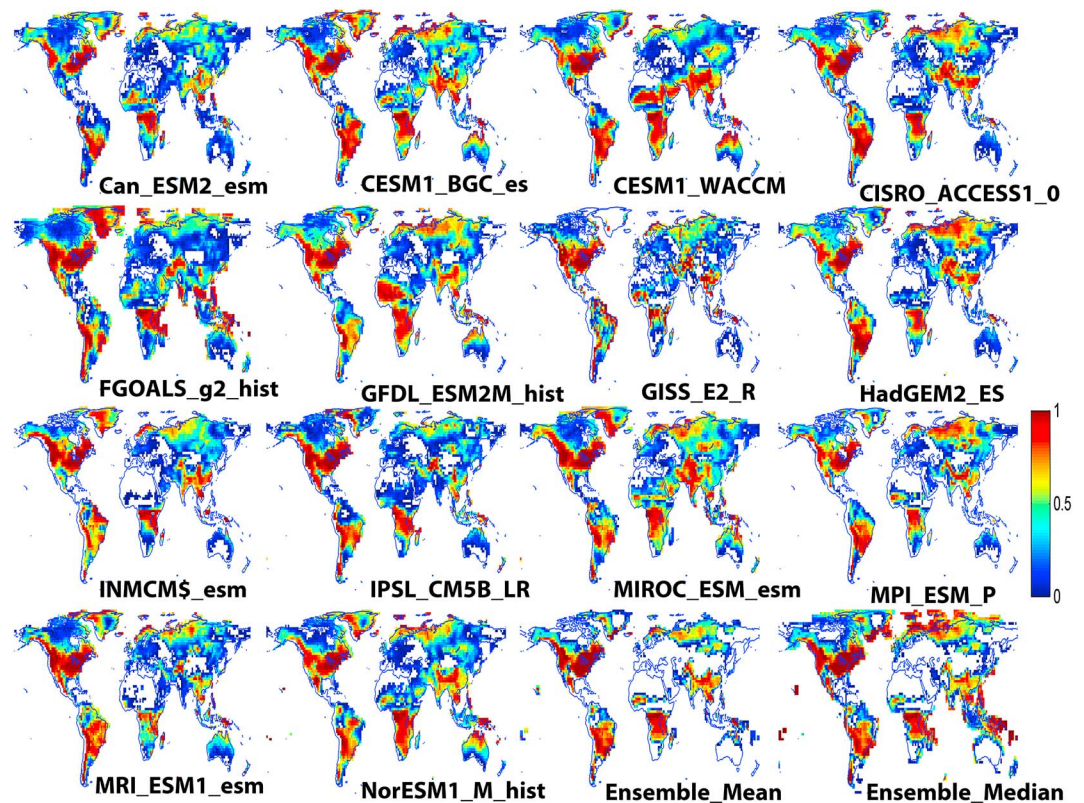

Figure 4. Volumetric hit index for $t = 75$ percentile VHI_{75} (with optimal value = 1) for selected CMIP5 precipitation simulations, and for their ensemble mean and median, with respect to GPCP observations.

computed for the entire distribution of precipitation ($t = 0$) and for values above the 75th percentile of the observations ($t \geq 75$ percentile of GPCP). Figure 3 presents the VHI when all precipitation data are included in the analysis ($t = 0$); white areas indicate no data below the choice of threshold t in either climate model simulations or observations. There is generally good agreement between model simulations and GPCP observations over many areas, especially in moist tropical regions such as Amazonia and southern Africa, and in temperate latitudes of Eurasia and North American, consistent with the findings of Liu *et al.* [2012]. However, there are obvious discrepancies not only over arid regions, especially northern Africa and the Middle East, but also the southwestern U.S. and Australia. From Figure 3, the ensemble mean and median appear to be superior to the individual climate models in reproducing the main GPCP precipitation patterns (see also Table 1 for global-average VHI values of the CMIP5 models and their ensemble mean and median).

It is acknowledged that the VHI is a skill score which assumes that a “perfect” model will be able to recreate the observations at each grid. However, the CMIP5 historical runs have large internal variability in precipitation, and one cannot expect the models to precisely reproduce precipitation observations, since they are not forced with prescribed, historical sea surface temperatures. Nevertheless, the VHI still provides valuable information as to what extent model simulations can capture historical satellite-based gauge-adjusted observations. Here the main purpose of using VHI is to show whether climate models, relative to each other, are consistent with observations. As shown, over many regions, many climate model simulations exhibit high VHI scores indicating reasonable consistency with observations.

Figure 4 displays VHI for the 75th percentile threshold of the observations (hereafter, VHI_{75}). When considering only data above this threshold, the performance of most models is seen to decrease substantially, indicating the presence of systematic biases in the CMIP5 simulations at higher quantiles. The VHI_{75} maps show that except over parts of high-latitude Eurasia, temperate North America, the lower Amazon, southeast Asia, and Central Africa, the model simulations lack skill above the 75% quantile. This is even more so for VHI at the 90th percentile threshold (figure not shown). It should be emphasized, however, that a low

Figure 5. Averaged bias (B) and 75th and 90th quantile bias values (QB_{75} and QB_{90} , all with optimal values = 1) for selected CMIP5 precipitation simulations, and for their ensemble mean and median, both before bias adjustment (solid lines) and after (dashed lines), all with respect to GPCP reference data.

value of VHI (or VHI_{75}) does not necessarily imply the absence of simulated precipitation but only that the models are simulating amounts below the local threshold (here the 75th percentile) of the GPCP reference observations. The results of both the VHI and QB₇₅ analyses confirm that there are biases in climate simulations of precipitation at higher quantiles, implying that more effort should be focused on improving precipitation physics in climate models, so as to more realistically simulate extreme values.

As an alternative to model physics improvements, bias adjustment algorithms have been developed to bring climate simulations closer to observational reference data [e.g., Li et al., 2010; Christensen et al., 2008; Haerter et al., 2011; Dosio and Paruolo, 2011; Xu and Yang, 2012]. Bias adjustment of global model simulations is necessary in order to supply more realistic estimates of precipitation (or other climate variables) to regional-scale models that can assess the impacts of climate on hydrology or agriculture, for example. The most common approach involves the removal of the mean-field bias of climate simulations relative to a given observed data set. Figure 5 plots global average global bias values of all 35 evaluated CMIP5 models for the thresholds of $t=0$ (all data), $t=75\%$ (QB_{75}), and $t=90\%$ (QB_{90}) percentiles of observations, both before and after removal of the mean-field bias. The models are sorted based on their overall bias values for better visualization. Here the mean-field bias is removed by multiplying the inverse of equation (1) by the original CMIP5 simulations. Considering all the data, the models exhibit global-average biases B between 0.75 and 1.25 (solid black line in Figure 5), and after mean-field adjustment, this overall bias can be removed (dashed black line in Figure 5). However, while the mean-field bias adjustment eliminates the overall bias, the figure indicates that this adjustment does not necessarily reduce the bias associated with a particular high or low quantile. Figure 5 instead confirms that a simple mean-field bias adjustment only marginally reduces such quantile biases.

In order to compare the spatial patterns of bias after mean-field bias adjustment, Figure 6 displays QB_{75} after removing the mean field bias of model simulations with respect to GPCP data (the bias-adjusted version of Figure 2). One can see that while some improvements in QB can be achieved through such adjustment, this is not the case over several areas such as portions of Australia, Africa, Eurasia, and North America. Thus, on average, CMIP5 models underestimate high quantiles of precipitation even after mean-field bias adjustment. This result underscores the importance of developing more sophisticated precipitation bias adjustment techniques, such as Watanabe et al. [2012] and Mehrotra and Sharma [2012], that go beyond consideration of only the mean statistics.

Figure 7 displays the globally averaged VHI, VHI_{75} , and VHI_{90} of climate model simulations against GPCP data before and after removal of the mean-field bias. The models are ranked on the x axis based on their overall VHI for better visualization. Similar to the case of QB, it is seen that VHI values drop substantially as the

Figure 6. Quantile bias ($t = 75$ th percentile, QB_{75} with optimal value = 1) maps after bias adjustment of CMIP5 precipitation simulations, with respect to GPCP observations.

threshold increases but that the mean-field bias adjustment significantly improves the VHI of the ensemble median. Unlike the bias metrics of Figure 5, the VHI values of the ensemble median in Figure 7 are consistently higher than those of the ensemble mean.

Figure 8 displays the spatial patterns of VHI_{75} of climate model simulations against GPCP data after mean-field bias removal (i.e., Figure 8 depicts results similar to those shown in Figure 4, but after bias adjustment).

Figure 7. Averaged volumetric hit index (VHI) and 75th and 90th percent quantile values VHI_{75} and VHI_{90} (with optimal values = 1) for selected CMIP5 precipitation simulations, and for their ensemble mean and median, both before bias adjustment (solid lines) and after (dashed lines), all with respect to GPCP reference data.

Figure 8. Volumetric hit index for $t=75$ th percentile (VHI_{75} , with optimal value = 1) after bias adjustment of selected CMIP5 precipitation simulations, all with respect to GPCP observations.

Compared with Figure 4, the VHI values in Figure 8 improve over certain areas, such as the United States, Amazonia, and Southeast Asia. In these regions, models such as FGOALS_g2_hist, GFDL_ESM2M_hist, CESM1-BGC_esm, and MIROC show high (~ 1) values of VHI_{75} . Overall, the VHI_{75} values of the ensemble mean and median are superior to those of individual models.

4. Summary and Conclusions

Reliable estimates of precipitation are essential for both research and practical applications. CMIP5 climate simulations provide both historical simulations and future projections of climate variables. Numerous studies have highlighted that climate simulations are subject to various biases and uncertainties [e.g., Brekke and Barsugli, 2012]. The objective of this study is to cross-validate CMIP5 historical simulations of precipitation relative to GPCP reference data, quantifying model pattern discrepancies (VHI metric) and biases (B and QB metrics) for both entire data distributions and their upper tails. It is acknowledged that observational data sets, like model simulations, are also subject to uncertainties, including systematic and random sampling errors [AghaKouchak et al., 2012]; over land, however, the GPCP data set is bias-adjusted using thousands of rain gauges [Adler et al., 2003], and hence, it should serve as a suitable reference for evaluation of continental precipitation in climate models.

From the results of the volumetric hit index (VHI) pattern analysis of the total monthly precipitation amounts, it is found that most CMIP5 simulations are in fairly good agreement with GPCP observations in many areas, but model replication of observed precipitation patterns over deserts and certain subcontinental regions (e.g., northern Eurasia and central Australia) is problematical. The VHI of the multimodel ensemble mean and median also are found to be superior to most CMIP5 model simulations overall.

Analyses of total biases (B) in CMIP5 simulations reveal that most models overestimate precipitation in regions of steep topography, while underestimating it leeward of the mountains, and over many other arid

regions. Moreover, while most climate model simulations show low B values over Europe, there are considerable intermodel variations in bias over Australia and Amazonia.

At high quantiles ($> 75\%$ and $> 90\%$) of the distribution of monthly precipitation, the quantile bias (QB) analyses indicate that CMIP5 simulations show more glaring discrepancies in precipitation amounts with respect to the GPCP satellite observations. While continuing to overestimate precipitation in regions of steep topography, the models generally underestimate it in tropical locations such as Amazonia, Central Africa, and southern Asia, as well as in broad swaths of the extratropics such as Australia, the arid regions of northern Africa and central Asia, and northern China, Russia, and Canada.

At high precipitation quantiles also, the CMIP5 models show substantially reduced agreement with the patterns of the GPCP reference data (e.g., the VHI_{75} metric for precipitation above the 75% quantile $< VHI$ over the entire distribution). Except over North America, Amazonia, and Central Africa, most CMIP5 simulations are lacking in predictive skill ($VHI_{75} \sim 0$) for the higher tail of the precipitation distribution. Note, however, that a low VHI_{75} does not necessarily imply the absence of locally simulated precipitation, only that its amount falls below the given reference data's threshold value. In addition, the ensemble mean and median precipitation at the higher quantiles are found to be superior to the individual climate model simulations when evaluated by the VHI_{75} , and VHI_{90} pattern measures, but not by the QB75 and QB90 bias metrics.

These results thus suggest that while today's climate model simulations are generally in agreement with satellite-based gauge-adjusted estimates of total monthly precipitation in many areas, they presently are not well suited for simulating upper quantiles of the precipitation distribution. Such distribution errors, which have persisted across CMIP phases [e.g., Dai, 2006; Sun et al., 2007; Stephens et al., 2010; Sillmann et al., 2013], are often characterized by a general tendency for the models to precipitate too frequently in light amounts but too rarely in the intense downbursts that are occasionally observed. In focusing on the upper tails of the precipitation distributions, the present study reveals such model intensity errors in a particularly stark way (e.g., in Figures 2 and 4).

The persistence of these upper tail errors in all the evaluated CMIP5 simulations is indicative of the presence of *general* deficiencies in the models. For instance, these systematic precipitation distribution errors do not seem to be very sensitive to intermodel differences in horizontal resolution (e.g., the MRI-ESM1_esm model, with a 160×320 grid, does not clearly outperform other coarser-resolution models in Table 1). Substantive differences in error structure also are not apparent between the “_esm” historical simulations with prescribed CO_2 emissions and those with prescribed CO_2 concentrations. Thus, it is likely that these systematic precipitation errors are due more to general model shortcomings in representing the dynamics or physics of climatic phenomena than to intermodel differences in greenhouse forcings or horizontal resolution.

For example, an ongoing preoccupation of model developers is to improve subgrid-scale parameterizations of convection, since precipitation errors tend to be especially large in the tropics [e.g., IPCC, 2007]. It is perhaps less widely appreciated that intense precipitation also often originates in frontal systems [Catto et al., 2012; Pfahl and Wernli, 2012] and that representative climate models tend to underestimate these extratropical precipitation events in spite of current abilities to adequately simulate the interaction of dynamics and moisture at model grid scale [Catto et al., 2010, 2013].

An underestimation or incorrect placement of intense tropical and extratropical precipitation is also clearly displayed by the CMIP5 simulations analyzed in the present study (e.g., in Figures 2 and 4). Such ubiquitous precipitation errors suggest that improvements, not only in model convective parameterizations but also in their representation of subgrid scale cloud microphysical processes that regulate droplet autoconversion, accretion, and throughfall [Lebsock et al., 2013; Van Weverberg et al., 2013], may be essential for better simulation of the observed global precipitation distributions.

Once such enhancements of model physics are in place, increases in model resolution are also likely to contribute to more realistic simulation of precipitation [Wehner et al., 2010; Champion et al., 2011]. This may be especially true in mountainous regions, where an accurate representation of the interaction of complex dynamics and steep moisture gradients is difficult to achieve solely through parameterization [e.g., Ghan et al., 2002; Qian et al., 2010].

Finally, this study demonstrates that while a simple mean field bias removal enhances the overall B and VHI values, it does not yield much improvement at high quantiles (i.e., QB75, QB90, VHI_{75} , and VHI_{90}). Thus, for

purposes of climatic impacts studies, it is important to develop more sophisticated techniques for adjusting the upper tail biases of global precipitation simulations in order to better replicate observed extreme values.

Acknowledgments

We would like to thank the reviewers for their thoughtful suggestions and comments that led to substantial improvements. The financial support for authors AM and AA was made available from the United States Bureau of Reclamation (USBR) award R11AP81451 and National Science Foundation award OISE-1243543. The contributions of author TJP were performed under the auspices of the Lawrence Livermore National Laboratory under contract DE-AC52-07NA27344. We acknowledge the World Climate Research Programme's Working Group on Coupled Modelling, which is responsible for CMIP, and we thank the climate modeling groups (listed in Table 1 of this paper) for producing and making available their model output. For CMIP, the U.S. Department of Energy's Program for Climate Model Diagnosis and Intercomparison provides coordinating support and leads the development of software infrastructure in partnership with the Global Organization for Earth System Science Portals. Also, the authors acknowledge the Global Precipitation Climatology Project (GPCP) team for providing and distributing The GPCP data sets.
