29 **1.0%). Using the volume model of Lutetia determined by the**  
30 **Rosetta OSIRIS camera, the bulk density, an important parameter**  
31 **for clues to its composition and interior, is  $(3.4 \pm 0.3) \cdot 10^3$  kg/m<sup>3</sup>.**

32 Asteroid (21) Lutetia, discovered in 1852, is one of the larger main belt  
33 asteroids. In 2004, it became the flyby target asteroid for the Rosetta  
34 mission. An important characteristic of an asteroid is its bulk density,  
35 derived from its mass and its volume. Although there are a number of  
36 asteroid mass determination techniques, by far the most accurate is  
37 spacecraft tracking during a close flyby.

38 The velocity of a spacecraft flying by a body of sufficient size and at a  
39 sufficiently close distance is perturbed by the attracting force of that  
40 body. The perturbed velocity is estimated from the additional Doppler  
41 shift of the transmitted radio signal in comparison with the expected  
42 Doppler shift of an unperturbed trajectory (1).

43 The Rosetta flyby geometry at Lutetia on 10 July 2010 was suboptimal  
44 because of the large flyby distance  $d=3168 \pm 7.5$  km, the high relative  
45 flyby velocity  $v_0=14.99$  km/s and the projection angle between the

46 relative velocity and the direction to Earth of  $\alpha=171.2^\circ$ , all of which  
47 reduced the post-encounter amplitude of the expected Doppler shift.

48 The final Doppler frequency shift six hours after the closest approach  
49 after correcting for contributions not associated with Lutetia (see  
50 Supporting Online Material SOM) is  $\Delta f=36.2\pm 0.2$  mHz (Figure 1). The  
51 value of  $GM$  from a least-squares fitting procedure and considering  
52 further error sources is determined to be  $GM=(11.34\pm 0.11)\cdot 10^{-2}$  km<sup>3</sup>s<sup>-2</sup>,  
53 corresponding to a mass of  $(1.700\pm 0.017)\cdot 10^{18}$  kg (error: 1.0%). The  
54 uncertainty in  $GM$  considers the error from the least squares fit mainly  
55 driven by the frequency noise (0.55%), the uncertainty in the Lutetia  
56 ephemeris introduced by the uncertainty in the flyby distance of  $\pm 7.5$  km  
57 (0.24%) and the considered uncertainty in the tropospheric correction  
58 introduced by the zenith delay model and the mapping function of the  
59 ground station elevation (0.8%). These contributions yield a total  
60 uncertainty of 1.0%. The values for  $GM$  and  $\Delta f$  agree within the error  
61 with the analytical solution (2). The derived mass is lower than other  
62 mass determinations of Lutetia from astrometry (see SOM).

63 One of the most important global geophysical parameters, which  
64 provide clues to the origin, internal structure and composition of Lutetia,  
65 is the mean (bulk) density, derived from the mass and the volume.  
66 Observations of the OSIRIS camera and ground observations using  
67 adaptive optics were combined to model the global shape.. The derived  
68 volume is  $(5.0\pm 0.4)\cdot 10^{14}$  m<sup>3</sup> (4). The volume leads to a bulk density of  
69  $(3.4 \pm 0.3)\cdot 10^3$  kg/m<sup>3</sup>. This high bulk density is unexpected in view of the  
70 low value of the measured mass. It is one of the highest bulk densities  
lutetia\_paper\_2011\_v15\_brevia.doc, [10.1088/1088-0808/20110808-2011](https://doi.org/10.1088/1088-0808/20110808-2011)

71 known for asteroids (5). Assuming that Lutetia has a modest  
 72 macroporosity of 12%, it would imply that the bulk density of its material  
 73 constituents would exceed that of stony meteorites. Unless Lutetia has  
 74 anomalously low porosity compared to other asteroids in its size range,  
 75 its high density likely indicates a nonchondritic bulk composition  
 76 enriched in high atomic number like iron. It may also be evidence for a  
 77 partial differentiation of the asteroid body as proposed by Weiss et al.  
 78 (6).

79

 82 and J. C. Marty, Precise mass determination and the nature of Phobos,  
 83 Geophysical Research Letters, Volume 37, Issue 9, CiteID L09202, 2010.

84 (2) As shown in (3), the expected final post-encounter Doppler shift of a two-  
 85 way radio carrier signal is ( $\alpha'=172.18^\circ$  is the direction to Earth projected into  
 86 the flyby plane,  $\beta=3^\circ$  is the direction angle to Earth above the flyby plane)

$$87 \quad \Delta f(t \rightarrow \infty) = 4 \frac{f_x}{c} \frac{GM}{d \cdot v_0} \cdot \sin \alpha' \cos \beta$$

88 Using the fit solution for Lutetia of  $GM = (11.34 \pm 0.11) \cdot 10^{-2} \text{ km}^3/\text{s}^2$  the  
 89 analytical result of the relation above is  $(36.4 \pm 0.4) \text{ mHz}$ .

33

### 34 **1. *Flyby and Observation***

35 The Rosetta spacecraft was tracked during the flyby at asteroid 21  
36 Lutetia on 10 July 2010 with NASA's Deep Space Network (DSN) 70-m  
37 antenna (DSS 63) near Madrid, Spain. Strong carrier signals at X-band  
38 ( $f_X=8.4$  GHz) and S-band ( $f_S=2.3$  GHz) were received throughout the  
39 flyby (Figure 1) except for a planned tracking gap from 5 minutes before  
40 closest approach ( $t_0$ ) to 40 minutes after  $t_0$  and a short gap of 26  
41 minutes starting at 192 minutes after  $t_0$ , when the uplink was  
42 accidentally dropped at DSS 63. The sampling time during the 10 hours  
43 of recording was one sample per second.

44

45 **Figure 1:** Received signal power at X-band from Rosetta +/- 3 hours around closest  
46 approach.

## 47 **2. Frequency Prediction**

48 The received carrier frequency from the actual flyby is compared with a  
49 carrier frequency prediction of a spacecraft motion unperturbed by the  
50 asteroid. This frequency prediction is based on a complex force model  
51 taking into account gravitational forces (Folkner et al., 2008) from the  
52 Sun and planets, and the largest asteroids Ceres, Pallas and Vesta, but  
53 not the target asteroid, and non-gravitational forces acting on the  
54 spacecraft (e.g. solar radiation pressure relative to a spacecraft macro-  
55 model with known optical parameters of each plane and the solar  
56 panels and their orientation at each time step). Also required are  
57 precise knowledge of the location of the ground station antenna phase  
58 center, and its behavior under forces like solid Earth tides and plate  
59 tectonic and a function of Earth rotation, precession and nutation  
60 (McCarthy & Petit, 2003). Relativistic propagation effects are  
61 considered up to second order (Häusler et al., 2007).

62 The frequency prediction is routinely computed for radio science data  
63 processing on the Mars Express and Venus Express missions (Pätzold  
64 et al., 2002).

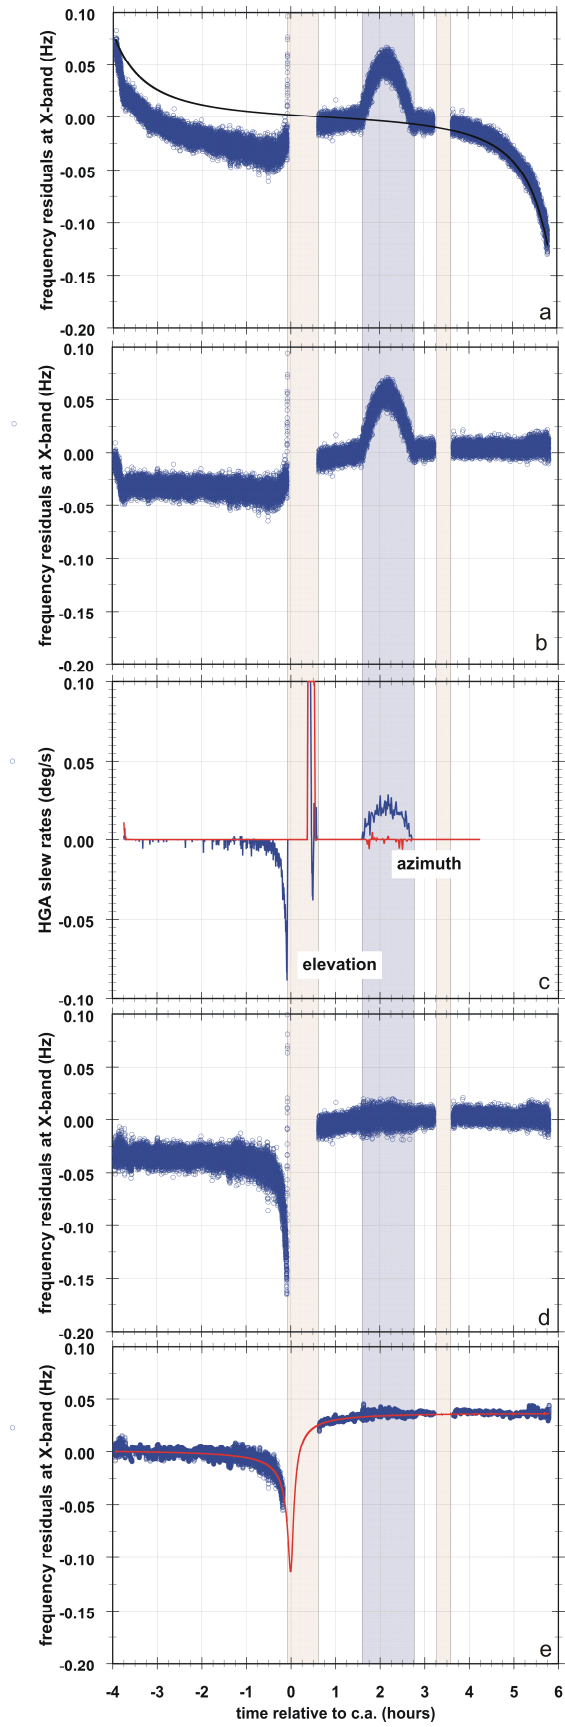

65

### 66 **3. Frequency residuals**

67 The frequency shift from the perturbed spacecraft motion caused by the  
68 attracting force of the asteroid is extracted from the frequency recorded  
69 in the ground station on Earth by subtracting the predicted unperturbed  
70 frequency. The difference between the observed perturbed and the  
71 predicted unperturbed Doppler shift is the raw frequency residual  
72 (Figure 2a).

73 **Figure 2 (next page):** Frequency residuals at X-band from  $t_0-4$  hours to  $t_0+6$  hours.  
74 Two tracking gaps are indicated (light red shaded zones) from  $t_0-5$  minutes to  $t_0+45$   
75 minutes as planned and from  $t_0+192$  minutes to  $t_0+218$  minutes when DSS 63  
76 accidentally dropped the uplink. a) raw uncalibrated frequency residuals (observed  
77 frequency minus predicted frequency). These raw residuals must be corrected for  
78 tropospheric propagation (solid line). b) Frequency residuals after tropospheric  
79 correction. The feature between  $t_0+95$  minutes and  $t_0+165$  minutes was caused by an  
80 HGA slew in elevation and azimuth, thereby producing an additional velocity  
81 component along the line-of-sight. c) HGA slew rates in azimuth (red) and elevation  
82 (blue). It is evident that the HGA generated an additional Doppler shift at the highest  
83 slew rates, in particular starting at  $t_0-15$  minutes. These contributions  
84 overcompensated the Doppler shift from the gravitational attraction of the asteroid. d)  
85 Frequency residuals corrected for the HGA slew rates. The large positive frequency  
86 residuals just before the first tracking gap are caused by the abrupt stop of the HGA  
87 slew. e) Filtered frequency residuals to reduce noise. The red solid line is a least-  
88 square fit to the data from which  $GM$  is determined.

89

90

91 **Figure 2**

#### 92 **4. Tropospheric correction**

93 The raw frequency residuals during the flyby contain a contribution  
94 caused by the propagation of the radio signal through the Earth's  
95 troposphere. The propagation is mainly affected by the temperature, the  
96 atmospheric pressure and the partial pressure of water vapor. These  
97 meteorological parameters are recorded at the ground station site and  
98 used for calibration.

99 The tropospheric refraction of the radio ray path in the Earth  
100 atmosphere consists of two components: i) the dry component, the  
101 non-water-vapor component of the atmosphere, and ii) the contribution  
102 of the highly variable water vapor content of the atmosphere( the so-  
103 called wet component). The correction for refraction in the Earth's  
104 atmosphere is calculated with models for the path delay and mapping  
105 functions which project the path delay onto the direction of the signal  
106 path for the wet and dry components.

107 The models from Saastamoinen et al. (1972) for the dry component,  
108 from Ifadis (1986) for the wet component, and the straightforward  
109 mapping functions from (Chao, 1972) were used to compute the  
110 tropospheric correction. The uncertainty in the wet component is much  
111 larger than that of the dry component.

112 The tropospheric correction is subtracted from the raw frequency  
113 residual (Figure 2a) to obtain the tropospherically corrected residual  
114 (Figure 2b). The difference between three correction models (Schüler,  
115 2001, Boehm et al., 2006, Petit and Luzum, 2010) for the zenith delay

116 and mapping functions was used to derive an systematic error estimate  
117 of the GM derivation.

118

## 119 **5. High Gain Antenna motion**

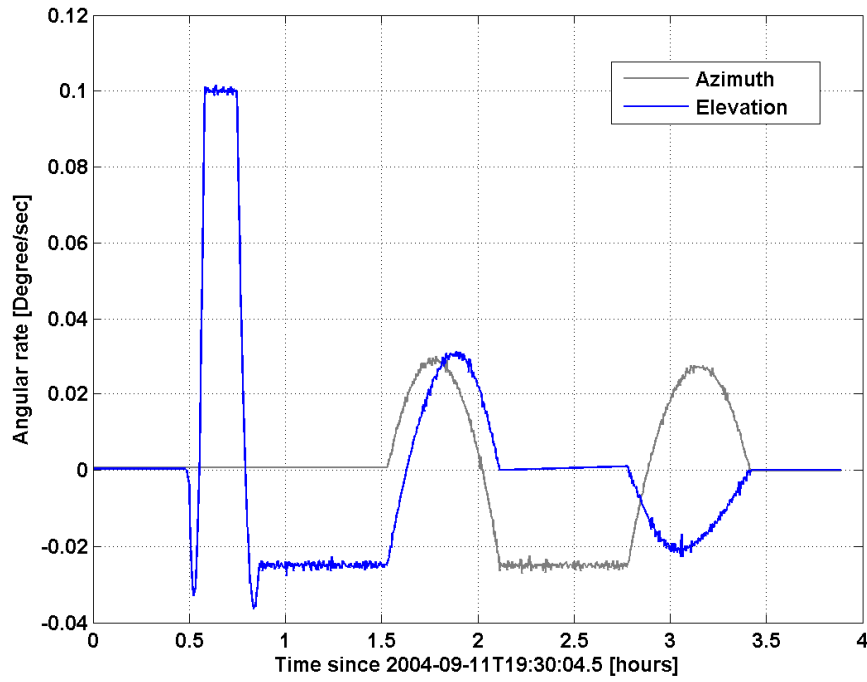

120 The steerable High Gain Antenna (HGA) of the spacecraft maintained  
121 Earth pointing until five minutes before closest approach, at which time  
122 the end position of the HGA motion was reached. The readjustment of  
123 the HGA resulted in a tracking gap of 45 minutes, including the time of  
124 closest approach. Pre-encounter flyby simulations, however, showed  
125 that stable and precise solutions for the mass can be achieved even  
126 with tracking gaps of several hours (Pätzold et al., 2010). While the  
127 Rosetta on-board instruments continued to track the asteroid, the HGA  
128 was articulated to reacquire Earth pointing. The varying HGA slew rates  
129 in azimuth and elevation (Figure 2c) induced an extra Doppler shift  
130 along the line-of-sight (LOS), which began to become significant at 15  
131 minutes before closest approach.

132 The rotation of the steerable HGA during the flyby induced an additional  
133 frequency shift on the observed radio signal which needs to be  
134 removed. This is done by applying the LOS component of  $\Delta \mathbf{v} = \boldsymbol{\omega} \times \mathbf{r}$ ,  
135 where  $\mathbf{r}$  is the vector from the center of mass (COM) to the phase  
136 center of the antenna and  $\boldsymbol{\omega}$  the rotation rate of the antenna. Because  
137 the COM changed during the motion of the HGA, the location of the  
138 COM was adjusted during the fitting process.

139 To demonstrate this motion correction, we used a pre-planned HGA  
140 motion maneuver performed in 2004. The HGA was rotated from  $-95^\circ$   
141 to  $-23^\circ$  in elevation with a maximum elevation rotation rate of  $0.1\%/sec$   
142 and from  $-34^\circ$  to  $34^\circ$  in azimuth with a maximum azimuth rotation rate of  
143  $0.03\%/sec$  (Figure 3). The maximum resulting frequency shift caused by  
144 the antenna rotation is about 300 mHz (Figure 4). The frequency shift  
145 caused by the antenna motion was corrected by using the above model  
146 and the resulting residuals are shown in Figure 5. It is seen that the  
147 frequency noise increased during the rotational motion caused by short  
148 term variations in the rotation rate. The additional frequency shift  
149 induced by the rotation of the HGA, however, is essentially removed  
150 from the frequency residuals, which are distributed about a mean value  
151 of zero.

152 The Doppler contributions from the HGA slew are evident in Figure 2b.  
153 The increase in frequency shortly before closest approach contrasts  
154 with the expected (Pätzold et al., 2010) Doppler shift signature of the  
155 asteroid. The post-encounter feature between 95 min and 165 min is a  
156 specially designed spacecraft slew for Philae observations. The  
157 contributions from the HGA slewing motion are removed to obtain the  
158 frequency residuals in Figure 2d, the calibrated and corrected Doppler  
159 shift caused by the asteroid between four hours before and six hours  
160 after closest approach.

161

162

163 **Figure 3:** Angular rates of the antenna motors in elevation and azimuth during a pre-  
164 planned maneuver in 2004. These values have been provided via the spacecraft  
165 housekeeping telemetry data.

166

167

168 **Figure 4:** Residual Doppler shift at X-band after subtracting the predicted frequency  
169 during the pre-planned maneuver in 2004. The large additional Doppler frequency shift  
170 is caused by the HGA motion in azimuth and elevation..

171

172

173 **Figure 5:** Residual Doppler shift from the pre-planned maneuver in 2004 after  
 174 correcting with the rotation rates of the HGA antenna motors in azimuth and elevation.  
 175 The rotation rates and angles were provided via the spacecraft housekeeping  
 176 telemetry data.

177

## 178 **6. Filtering and adjustment**

179 The frequency residuals in Figure 2d were filtered at an integration time  
 180 of 18 seconds for noise reduction.

181 Two different types of filters are used for data noise reduction: a Kaiser  
 182 window filter and a moving average filter (Buttkus, 2000). Both filters  
 183 are applied consecutively in forward and reverse direction ensuring a  
 184 zero phase. The cut-off frequency  $f_c = 0.028$  Hz Kaiser window filters  
 185 and the integration time  $\Delta t = 18$  seconds of the moving average filter

186 were determined a priori with respect to the mass sensitivity. This  
187 approach avoids elimination of information in the data about the mass  
188 of the body and ensures that only noise is removed. The noise of the  
189 Lutetia flyby data was reduced in this step by more than a factor of two  
190 from 5.7 mHz to 2.6 mHz.

191 It is known from our experience with Mars Express and Venus Express  
192 radio science data processing that the frequency residuals can show a  
193 constant pre-event bias on the order of 10...50 mHz caused by  
194 contributions not considered in the prediction. In the Lutetia case, these  
195 contributions are not connected with the attracting force of the asteroid.  
196 The pre-encounter frequency residual bias of -32 mHz has been  
197 removed. This adjustment assumes a zero mean for the pre-encounter  
198 frequency residuals from  $t_0-4$  hours to  $t_0-3$  hours. The Hill sphere of  
199 influence of Lutetia (radius: 25,000 km) was entered at  $t_0-0.5h$ .

200

## 201 **7. *Fit and uncertainty***

202 A least squares fit to the filtered curve (Figure 2e) yields a solution for  
203  $GM$ , an adjusted pre-encounter state vector, an adjusted solar radiation  
204 pressure constant and the scale factor for the motion of the HGA phase  
205 center with respect to the spacecraft center-of-mass.

206 The final Doppler frequency shift six hours after the closest approach is  
207  $\Delta f = (36.2 \pm 0.2)$  mHz (Figure 2e).

208 The mass and the other parameters were estimated with a weighted  
209 least-squares method. The initial velocity vector, the scale factor for the

210 solar radiation pressure, the center of mass adjustment factor and the  
 211 mass of Lutetia were fit using the frequency residuals. An initial state  
 212 vector of the Rosetta spacecraft at  $t_0-4$  hours is taken from the most  
 213 actual SPICE-kernel<sup>1</sup> provided by the ESOC Flight Dynamics team as a  
 214 first guess for the fitting procedure.

215 The change  $\delta x$  of the initial parameter set  $x$  iteratively aligning the  
 216 measurement and the model is obtained from

$$217 \quad \delta \mathbf{x} = (\mathbf{J}^T \mathbf{W} \mathbf{J} + I \alpha)^{-1} \mathbf{J}^T \mathbf{W} \boldsymbol{\varepsilon},$$

218 where  $\mathbf{J}$  is the Jacobi matrix, containing the partial derivatives of  
 219 parameter set  $x$ ,  $\mathbf{W}$  the weighting matrix containing the standard  
 220 deviation of the measurement,  $\boldsymbol{\varepsilon}$  the difference between model and  
 221 measurement,  $I$  the identity matrix and  $\alpha$  is a damping factor. The  
 222 damping factor serves as a numerical stabilization of the solution  
 223 against ill-posed parameters (Aster et al., 2005). The iterative process  
 224 is applied until the solution converges, i.e. measurement and models  
 225 are aligned. The inverse of the term in parenthesis is computed using  
 226 singular value decomposition (Press et al., 1986).

227 The error of each parameter is derived from the diagonal terms of the  
 228 covariance matrix

$$229 \quad \mathbf{P} = (\mathbf{J}^T \mathbf{W} \mathbf{J})^{-1}.$$

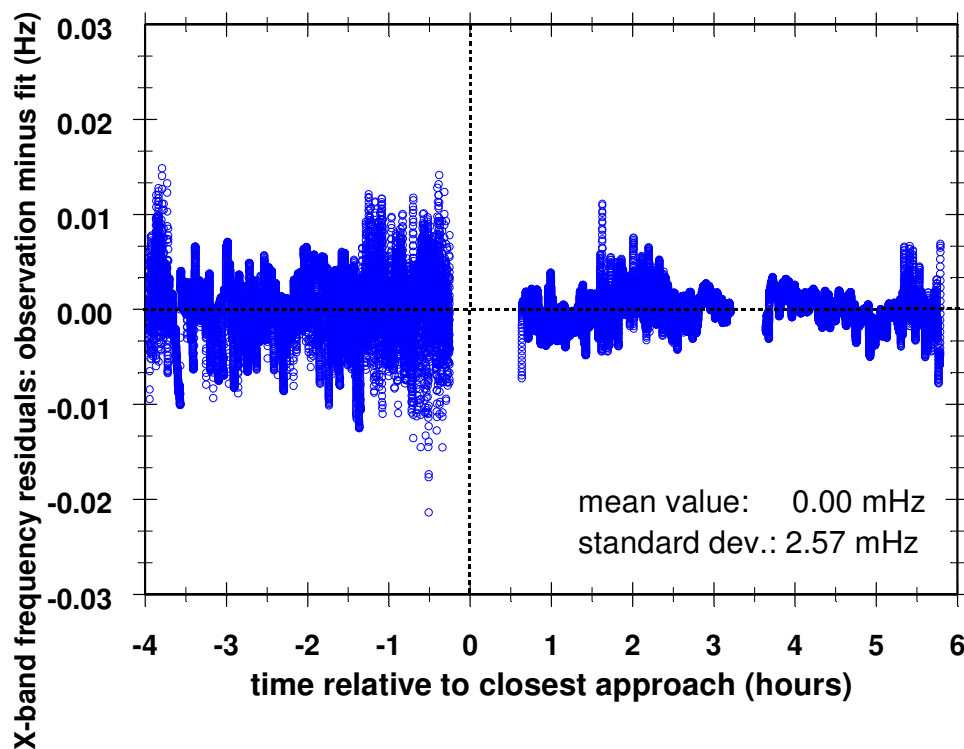

230 The value of GM from the above described fitting procedure and  
 231 considering further error sources is determined to be  $GM = (11.34 \pm$

---

<sup>1</sup> The SPICE Kernel ORHR\_\_\_\_\_00109.BSP is available from  
 ssols01.esac.esa.int for all Rosetta experiment teams and is considered as a  
 long term planning orbit file for experimental purposes.  
 lutetia\_paper\_2011\_v15\_som.doc, 09.08.2011

232  $0.15) \cdot 10^{-2} \text{ km}^3 \text{ s}^{-2}$  corresponding to a mass of  $(1.700 \pm 0.017) \cdot 10^{18} \text{ kg}$   
 233 (error: 1.3%). The uncertainty in  $GM$  considers the error from the least  
 234 squares fit mainly driven by the frequency noise (0.55%), the  
 235 uncertainty in the Lutetia closest approach time introduced by the  
 236 uncertainty in the flyby distance of  $\pm 7.5 \text{ km}$  (0.24%) and the  
 237 considered uncertainty in the tropospheric correction introduced by the  
 238 mapping function of the ground station elevation (0.8%) yielding a total  
 239 uncertainty of 1.0%.

240 The post-fit Doppler residuals, the difference observation minus the fit  
 241 are shown in Figure 6.

242

243 **Figure 6:** Post-fit residuals after subtracting the least-squares fit from the filtered  
 244 observation (Figure 2e).

245

## 246 **8. Comparison and discussion**

247 The values for  $GM$  and  $\Delta f$  agree within the error with the analytical  
 248 solution. As shown in (Pätzold et al., 2010), the expected final post-  
 249 encounter Doppler shift of a two-way radio carrier signal is

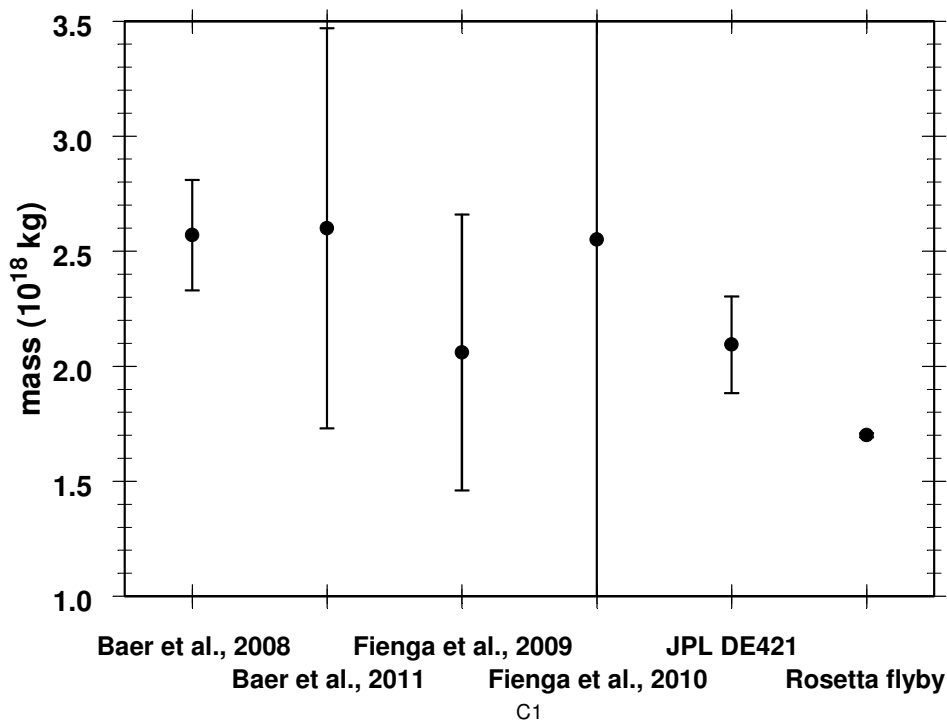

$$250 \quad \Delta f(t \rightarrow \infty) = 4 \frac{f_X}{c} \frac{GM}{d \cdot v_0} \cdot \sin \alpha' \cos \beta$$

251  $\alpha' = 172.18^\circ$  is the direction to Earth projected into the flyby plane,  $\beta = 3^\circ$   
 252 is the direction angle to Earth above the flyby plane.

253 Using the fit solution for Lutetia of  $GM = (11.34 \pm 0.11) \cdot 10^{-2} \text{ km}^3/\text{s}^2$  the  
 254 analytical result of the relation above is  $(36.4 \pm 0.4) \text{ mHz}$ .

255 The mass estimate from the Rosetta flyby is compared in Figure 7 with  
 256 the asteroid masses derived from astrometry or perturbation  
 257 calculations. The derived mass is lower than other mass determinations  
 258 of Lutetia from astrometry (Baer et al., 2011; Fienga et al., 2008; Fienga  
 259 et al., 2010; Folkner et al., 2009). A systematic bias is apparent: Baer  
 260 et al. (2010) derived a mass value of  $(2.59 \pm 0.24) \cdot 10^{18} \text{ kg}$  for Lutetia  
 261 from asteroid/asteroid perturbations, which is 70% larger and has an  
 262 error of 15%. A more recent derivation (Baer et al., 2011) yields  
 263  $(2.6 \pm 0.87) \cdot 10^{18} \text{ kg}$  where the error increased by a factor of 3. Fienga et  
 264 al. (2008) derived a mass value of  $(2.06 \pm 0.6) \cdot 10^{18} \text{ kg}$  from the  
 265 influence of Lutetia on the motion of the planet Mars, which is 20%  
 266 larger than Baer et al. (2010) and has an uncertainty of 30%. Again, a  
 267 more recent derivation (Fienga et al., 2010) of  $(2.55 \pm 2.34) \cdot 10^{18} \text{ kg}$  is  
 268 closer to Baer et al. (2008, 2011) but has an error of 92%. The Jet

269 Propulsion Laboratory (JPL) ephemeris DE421 (Folkner et al., 2009)  
 270 lists the mass of Lutetia as  $(2.094 \pm 0.21) \cdot 10^{18}$  kg with an error of 10%.  
 271 Each precise direct mass determination of a large asteroid is therefore  
 272 a valuable contribution to solar system dynamics.

273

274 **Figure 7:** Comparison between mass determinations of (21) Lutetia by astrometry and  
 275 the Rosetta direct mass determination. The Rosetta error bar is smaller than the  
 276 measurement point. The earlier derived values are systematically higher.

277

278 The most important global geophysical parameter, which provides  
 279 clues for the origin, internal structure and composition of Lutetia, is the  
 280 mean (bulk) density, derived from the mass and the volume. The  
 281 different pre-encounter values for the volume, as discussed earlier, vary  
 282 over large ranges of the order of 20%. The precise mass value from  
 283 Doppler observations during the Rosetta flyby leaves the volume as the  
 284 only significant error source for the bulk density. Observations of the  
 lutetia\_paper\_2011\_v15\_som.doc, 09.08.2011

285 OSIRIS camera and ground observations using adaptive optics were  
286 combined to model the global shape. The derived volume is  $(5.0 \pm 0.4)$   
287  $10^{14} \text{ m}^3$  (Sierks et al., 2011). A large part of the asteroid could not be  
288 observed during the flyby itself but the combination with adaptive optics  
289 images from other viewing directions than from the flyby, the  
290 requirement of principal axis rotation and the agreement with the  
291 KOALA (Carry et al., 2010) model with the imaged part of the asteroid  
292 constrain the error in the volume to 8%. Although the absolute value of  
293 the volume determined by Lamy et al. (2010) is confirmed, the error  
294 decreased by little more than a factor of 2.

295 The volume leads to a bulk density of  $(3.4 \pm 0.3) \cdot 10^3 \text{ kg/m}^3$ . The high  
296 bulk density is unexpected in view of the low value of the measured  
297 mass. It is one of the highest bulk densities known for asteroids.  
298 Assuming that Lutetia has a modest macroporosity of 12%, it would  
299 imply that the bulk density of its material constituents would exceed that  
300 of stony meteorites. Unless Lutetia has anomalously low porosity  
301 compared to other asteroids in its size range, its high density likely  
302 indicates a nonchondritic bulk composition enriched in high atomic  
303 number like iron. It may also be evidence for a partial differentiation of  
304 the asteroid body as proposed by Weiss et al. (2011)

305

## 306 **Acknowledgements**

307 The Rosetta Radio Science Investigation (RSI) experiment is funded by DLR  
308 Bonn under grants 50QM1002 (TPA, BH) and 50QM1004 (MP, MH, ST, MKB)  
309 and under a contract with NASA (SWA, JDA). We thank T. Morley (ESOC) for
